## ABSTRACT

This thesis explores the theoretical and practical problems encountered in using Multiple Attribute Utility Theory
to assign capability measures to military weapon systems.
Two experiments were conducted, the first employed the
classical form of data representation and the second utilized
piecewise linear approximations as a practical alternative.
It was concluded that Multiple Attribute Utility Theory
appears to be a significant step forward in the search for
a valid measure of arms transfers.

# I. INTRODUCTION

Centuries ago, the transfer of arms from one nation to another was a relatively simple process with consequences the average man could easily understand. A bow and arrow involved one man, had an estimable reloading time and could kill up to a measureable distance. Today, however, modern technology has produced a class of weapons whose complexity and sophistication defy the simple, subjective calculations that faced the merchants and analysts of primitive weapons.

One needs something other than intuition or a "gut feeling" to reliably assess the military, political, and economic implications of selling, say, twenty F-15 "Eagles" to a nation in the Middle East. Yet, it is in this arena of reliably assessing military capabilities among third world nations that some of the most pressing methodological problems exist. Dollar valuations, inventory comparison and military utility have all been examined and to date, have not provided a satisfactory indicator of military capability.

As an alternative, Multiple Attribute Utility Theory

(MAUT) appears to provide a more consistent estimator. MAUT

is an analytic device with roots in the field of economics.

It combines a class of psychological measurement models and scaling techniques to distill multi-dimensional alternatives into a single, ratio index.

This thesis will examine the theoretical and practical problems encountered in using MAUT to assign capability measures to weapon systems which take into account the variables that are relevant in a third world context. Research has been confined to the analysis of air-to-air weapon systems but the analogy to other platforms is readily made. All data and results are presented so that further research may begin from this point.

Chapter II reviews some of the dominant methodologies that have appeared to date. It also discusses Multiple Attribute Utility Theory with its pertinent forms and assumptions. Additionally, it introduces the factors considered to be descriptive of fighter aircraft. Chapter III presents a small sample survey in which the necessary data for applying MAUT to fighter aircraft is presented. data are used to evaluate the F4J "Phantom" with Israeli and Egyptian pilots. The respondents for this survey were experienced aviators who possessed a knowledge of utility curves and their uses. Chapter IV examines a possible alternative to the classical form of data collection. Instead of the required utility curves, piecewise linear approximations are substituted. These approximations contain three critical points and were derived from the responses of 200 members of the Red River Valley Fighter Pilots Association. It is hoped this technique will provide the policy maker with a relatively simple procedure for collecting data and simultaneously broadening his

data base. Chapter V summarizes the major conclusions and observations noted during the course of this research.

# II. METHODOLOGIES FOR ASSESSING ARMS TRANSFERS

#### A. REVIEW OF CURRENT METHODOLOGIES

This section will summarily review the dominant methodologies for measuring arms transfers. These are the dollar value, numerical/inventory comparisons and military capability approaches. It is hoped that this brief discussion will generate an appreciation for the difficulties encountered in reliably assessing arms transfers.

# 1. Dollar Value Method

In 1969, the Stockholm International Peace Research Institute (SIPRI)[1] began a formal effort to monitor arms flows between the rich industrial powers and the rest of the world. SIPRI employed the dollar-value technique and collected their data "from a wide variety of sources." Basically, analysts employing the dollar-value technique use price to quantify the volume and direction of arms flow. At first glance, this may seem to be a reasonable measure of capability since price information is understood easily, is measured on a ratio scale (thus enjoying all the properites of the real number line) and is available in most instances. A closer examination, however, reveals four major weaknesses of this method.

a. Inflation and fluctuating exchange rates often precipitate a situation where the increase in arms

<sup>1</sup> Stockholm International Peace Research Institute, The Arms Trade with the Third World, p. VI, Almquist and Wilksells Boktryckeri AB, Uppsala, 1971.

expenditures corresponds to a decrease in the number of weapons actually transferred. Analysts have attempted to alleviate this problem by adjusting yearly figures to reflect some arbitrary exchange rate. Unfortunately, these fluctuations usually are so rapid they cannot be compensated for and the weapon's true value at the time of the transaction is unclear.

- b. Much uncertainty exists regarding cost data for foreign arms transfers -- particularly in communist countries. When this information is lacking or insufficient, a tendency exists to evaluate these figures in terms of Western production costs. As Sivard states, "... although statistical work on such parity rates is underway, under international sponsorship, the availability of purchasing power parities for a large selection of countries is some distance in the future. Hence, an acknowledged doubt exists concerning foreign cost data and its reliability.
- c. In many instances, arms are sold from one nation to another for as little as one-tenth to one-hundredth of their initial cost. 4 Often, the reasons for such favorable terms are:

The International Transfer of Conventional Arms, p. 1, Washington: Arms Control and Disarmament Agency, 1973.

<sup>&</sup>lt;sup>3</sup>Sivard, Ruth L., <u>World Military and Social Expenditures</u> 1974, p. 30, WMSE Publications, 1974.

<sup>&</sup>lt;sup>4</sup>Mihalka, Michael, <u>Understanding Arms Accumulation: The Middle East As An Example</u>, p. 14, University of Michigan (MIMEO), 1973.

- (1) the supplier country may be depleting excess stock;
- (2) the supplier country may no longer have any use for that particular equipment; or
- (3) the transfer of arms may be a rider to a much larger deal.

Clearly, the real cost of such transactions has been obscured by the extremely favorable terms of sale.

d. Finally, price is an unreliable indicator of the qualitative differences in arms. Consider the F-14 and the C5A. They are both examples of costly military systems yet a marked difference exists in their military offensive power. Gross differences such as these need to be discerned if one is to properly assess the true military worth of arms transfers.

# 2. Numverical/Inventory Approach

With the numerical/inventory approach, countries' capabilities are compared on the basis of their respective inventories, say, of MIGs and Phantoms. In some respects, this approach is more reliable than the dollar-value method since major weapons are difficult to hide and a country's supply of these items are usually public knowledge. However, correlating inventories with capability is difficult because of the qualitative differences among the various weapons systems. Just how much better is an F4E with a pilot from Country A than a MIG-19 with Country B's pilot? Certainly, lessons learned from Vietnam and the two Middle East wars

should confirm the notion that inventory balance sheets are not a reliable indicator of military capability.

# 3. Military Capability Models

In an effort to overcome the shortcomings of the dollar-value and numerical/inventory methodologies, analysts have employed various indexing techniques for juxtaposing weapons systems along some capability scale [2].

One of the most intuitively pleasing approaches to scaling military capability is the factor analysis technique. This process synthesizes a collection of interval data into a set of summary dimensions and shows the degree to which discrete variables are associated with each summary dimension. Mihalka [3] and Snider [4], proponents of this approach, employ similar hypotheses whereby aircraft are categorized into two summary dimensions. Milhalka considers fighter aircraft to fall somewhere along the two different combat missions of "attack" and "defense" while Snider feels they should be separated into "interception/air superiority" and "tactical support ground attack." After making these a priori decisions about aerial combat dimension, Mihalka and Snider separately factor analyzed various data sets and were able to reduce each aircraft to a single, interval score (an example of Snider's aircraft scores is provided in Figure 1). These interval scores, however, are inherently unstable. This is because there is no natural or fixed origin with interval measures. For example, consider the Farenheit scale used to measure temperature. The "zero"

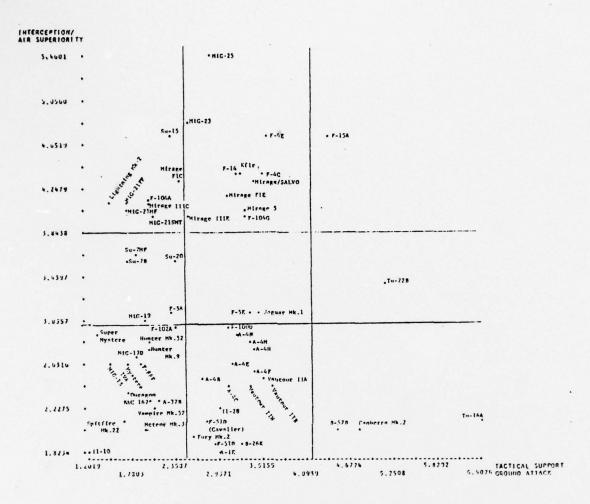

Figure 1. Capability Mix of Principal Combat Air-craft Transferred to the Third World, 1945-1973.5

Snider, L. W., Arabesque: Untangling the Patterns of Supply of Conventional Arms to Israel and the Arab States and the Implications They Have for American Supply of "Lethal Weapons" to Egypt, p. 70, Figure 1, The Claremont Graduate School, July 1976.

for this system was arbitrarily chosen to fall 32 (Farenheit) degrees below the freezing point of water. It could have easily been 31 or 33 Farenheit degrees below the freezing point of helium. Since there is never a lack of temperature, there is virtually an infinite number of zero points for this system or any system using interval measurement. By contrast, techniques that achieve ratio measurement have an inviolate zero point, identical in every respect to the zero of the real number line. Thus, analysts evaluating the various methodologies measuring arms flows must be critical of the theory and the level of measurement that the particular technique achieves. As stated earlier, factor analysis does not produce ratio data and perhaps the problems generated by such approaches are best illustrated by the following example.

"Consider, first, the process leading to the aircraft inventory capability scores. The first step of this calculation involves adjusting the derived weapons capability scores so that there are no negative or zero values. Mihalka accomplishes this by adding 0.1 (selected arbitrarily) to the absolute value of the lowest factor score and adding the resulting sum to each aircraft score. The effect is to move each system in a positive direction along the interval scale by the amount. Recall that this is permissible with interval measurement since the information is preserved by a linear transformation. Multiplying these adjusted values by varying inventories to obtain composite country scores is tenuous, however ... An example will illustrate this. Suppose the derived factor score for aircraft A is 2.0 and for aircraft B, 1.0, along the offensive dimension. If a country had an inventory of 25 As, the country capability score would be 25 x 2.0 = 50.0. Similarly, if a second country had 50 Bs, its capability score would also be 50.0. Clearly, this would be a situation of parity. Now consider the transformation of the individual factor scores by an arbitrary value of 0.5, i.e., aircraft A = 2.5 and aircraft B = 1.5. Multiplying these adjusted capability scores by the same

country inventories yields a capability score of 67.5 for the first  $(25 \times 2.5 = 67.5)$ , and 75.0 for the second  $(50 \times 1.5 = 75)$ . A situation of equality has suddenly become an advantage for the second country with any change in the number or type of weapons."

In summary, the problem of reliably measuring arms transfers remains unsolved [5]. Thus, new methodologies for solving this problem are constantly being evaluated and one such methodology, Multiple Attribute Utility Theory, is discussed and examined in the following chapters.

#### B. MULTIPLE ATTRIBUTE UTILITY THEORY

# 1. Rationale

Theoretically, Multiple Attribute Utility Theory combines a class of psychological measurement models and scaling techniques that can be applied to the decision making process when an assessment of multi-facet alternatives is necessary. Practically, MAUT provides the analyst with a methodology for measuring arms transfers on a ratio scale yet avoids the difficulties encountered by the dollar value, numerical/inventory, and military capability techniques.

MAUT does this by first, decomposing weapon systems into their basic elements, second by ascertaining the utility curve and factor weight for each element, and third, by constructing a model to evaluate weapon systems of the same class. Once this process is complete, MAUT enables the

<sup>6</sup> Legrow, Allan W., Measuring Aircraft Capability for Military and Political Analysis, p. 36, Masters Thesis, Naval Postgraduate School, Monterey, CA, March 1976.

analyst to "score" a particular weapon system, say fighter aircraft, on the basis of its platform design, weapon capabilities, pilot experience and the technical level of the consumer nation. For example, suppose Country A has a fighter aircraft with a score of 10 and Country B has a fighter aircraft with a score of 5. Then Country A has the superior fighter and Country B would need two of their aircraft for every one of Country A's to achieve parity. It should be noted, however, that these indices are only meaningful to aircraft of identical classes. That is, no conclusions can be drawn from an air-to-ground system with a score of 7 and an air-to-air system with a score of 14, since the elements underlying each evaluative model are different.

# Theory/Application

There are two basic forms [6] to the Multiple Attribute Utility Function and they are:

a. The Multiplicative Form

$$1 + K \cdot U(\overline{X}) = \prod_{C=1}^{N} [1 + K \cdot K_{\underline{i}} \cdot U_{\underline{i}}(X_{\underline{i}})]$$
 (1)

where  $U(\overline{X})$  = multi-attributed utility function (In fighter aircraft, U(X) would designate the entire system.)

 $U(X_i)$  = the utility function for attribute i

 $X_{i}$  = a specific attribute

 $K = constant; -1 \le k < \infty$ 

 $K_i$  = subjective weight for  $X_i$ ;  $0 \le K_i \le 1$  (If attribute i were dash speed, then  $K_i$  represents

dash speed's weight or importance to the functioning of the entire system.)

b. The Additive Form

$$U(\overline{X}) = \sum_{i=1}^{N} K_{i} \cdot U_{i}(X_{i})$$
 (2)

where  $U(\overline{X})$  = multi-attributed utility function

U(X;) = utility function for attribute i

X, = a specific attribute

 $K_i = \text{subjective constant for } U(X_i); 0 \le K_i \le 1;$ 

$$\sum_{i=1}^{N} K_{i} = 1$$

Each form requires the same data for input, that is, a utility curve and a factor weighting for each factor. The different forms reflect the combinatorial relationship the factors bear towards one another. Before discussing the two forms and their attendant properties, a discussion of the data and how they were collected will appear first. The discussion begins with the general concepts encountered in utility theory and concludes with the factor weighting of each factor.

# c. Utility Curves

The utility curve is a concept generally encountered in the field of economics. It is a graphic tool that displays the user's preference or utility between alternatives. It entails two basic assumptions, (1) the person who draws such a curve will always act in a rational manner; and (2) this person is aware of his alternatives. 7

Henderson and Quandt, Microeconomic Theory, p. 6, McGraw-Hill, 2nd Edition, 1971.

These assumptions have precipitated much controversy in the professional literature. It is often argued that they are naive and unrealistic. The theory, however, does not imply these assumptions always hold, it merely states that if they hold, the derived utility functions are valid. It is up to the person who employs such techniques to determine if the assumptions of rationality apply in a particular analytic situation. For the purposes of this research, it is assumed these assumptions are satisfied where needed.

Mapping utility curves in Multiple Attribute
Utility Theory requires a series of difficult decisions.
One, in particular, leads to the derivation of ratio measurement, a level of measurement previously identified as crucial in the measurement of arms transfers. To illustrate, a sample curve (Figure 2) depicting the dash speed of a fighter aircraft is presented and discussed.

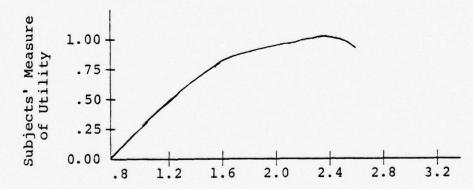

Figure 2. Sample Utility Curve for Dash Speed.

The vertical axis represents the judge's utility scale and is annotated from 0 to 1. Zero implies no utility or value

and 1.0 implies the maximum utility or value. The horizontal axis represents the factor being evaluated. In this case, the factor is dash speed of a fighter aircraft (airto-air) and the speeds range from MACH .8 to MACH 3.2. An interpretation of this curve would reveal its author felt that if the dash speed of an aircraft was less than MACH .8 it had no utility as a fighter aircraft. In other words, a dash speed less than MACH .8 would be unacceptable in the fighter community. Similarly, a dash speed of MACH 2.4 represents the optimum speed for this factor. Any further increases would be of marginal value. The shape of the curve also conveys much information. The sharp rise from MACH .8 to MACH 1.6 indicates large capability shifts per unit increase in speed. If the vertical scale was changed to dollars, the analogy would infer a greater return on the dollar per unit increase in speed than anywhere else on the graph. Similarly, the slow rise from MACH 1.6 to MACH 2.4 (the optimum) indicates small capability shifts per unit increase of speed.

Deriving such curves is a stringent process.

The steps of the process are summarized as follows:

(1) Determine an upper and a lower limit for each attribute. The lower limit should represent the point of class distinction 8 and the upper limit, a value such

<sup>&</sup>lt;sup>8</sup>That is, if the attribute were to assume a smaller value it would fall into a different class. For example, if a race car has a lower limit of 120 mph, this would mean any car which could not travel at least 120 mph would not be in the class of race cars, it would be in the class of passenger cars, etc.

that any further increases would only result in marginal returns. The lower limit is crucial since it established the property of ratio measurement. The assumption required is that the lower limit, by definition, represents a "natural" fixed origin. That is, as far as the judge is concerned, this point represents the absolute zero point for the attribute in question. Thus, if the reader considers this a judicious assumption, ratio measurement has been achieved.

(2) The body of the curve is ascertained through a series of probabilistic decisions. For example, if the analyst was attempting to establish the value associated with the 50th utile (i.e., the dash speed that corresponds to .5 on the vertical axis) the analyst would present the judge with two theoretical alternatives, say, A and B. The contents of alternative A are defined by the utile considered and usually represent the extreme cases. Alternative B is defined by the judge (i.e., an expert in the particular field of interest) and the decision for this alternative, when contrasted with alternative A, establishes the desired utile. Using the values of this example, alternative A represents the situation where, if chosen, there is a 50% chance the factor would be designed into an aircraft to reflect the optimum (MACH 2.4) and a 50% chance the factor would be designed into an aircraft at its minimum value (MACH .8). Alternative B, on the other hand, would guarantee the factor be designed into the aircraft at a value of "X". This value of "X" is determined by the judge.

It should reflect a value that renders the judge indifferent between alternative A and B.

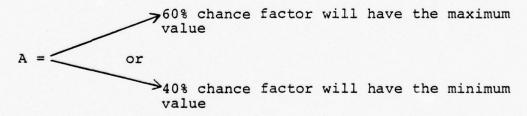

Pictorially, the alternatives would appear

50% chance factor will have the maximum value

or

50% chance factor will have the minimum value

The judge must decide what value, if substituted for "X" would make him/her indifferent between alternative A and B. Whatever value is determined for "X" is the 50th utile. In other words, the analyst is making the judge establish the point where the risk involved in alternative A seems equally attractive as the "sure thing" of alternative B. If the analyst were attempting to establish the 60th utile, the alternatives would appear as

B = 100% guarantee factor will have some value "X"

(If it was the 40th utile, the probabilities in alternative A would be reversed.)

The judge is informed that "indifference" between alternatives A and B means he/she would accept the flip of a coin to determine whether the consequences of alternative A or alternative B are to establish value of the said factor. The judge is further informed that the ramification of his choice will be reflected into future combat aircraft.

# d. Subjective Weights (K;)

Having the judge subjectively evaluate each attribute's contribution to the overall process entails the second major assumption for ratio measurement. In short, judgmental measurement theory hypothesizes that a definite regularity exists in value judgments. Thus, it is argued that the judge's decision reflect enough precision to achieve ratio measurement. Torgerson [7], however, states that some judgmental measuring techniques such as the subjective estimate and constant sum methods actually produce ratio measurements. Once the judge has evaluated each factor's weight and utility curve, the analyst then faces the task of combining these judgments into a final utility score for the entity being assessed (e.g., fighter aircraft). This is done by determining which, if any, of the following properties have been satisfied. They are, as defined by Giaque :

Giaque, William C., Prevention and Treatment of Streptococcal Sore Throat and Rheumatic Fever - A Decision Theoretic Approach, p. 10-18, Ph.D. Thesis, Harvard University, November 1972.

- (1) <u>Utility Independence</u>. Assume consequence  $\overline{X} = (X_1, \dots, X_N)$  with utility U(X). If  $X_{\overline{1}} = (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_N)$ ,  $X_i$  is utility independent of  $X_{\overline{1}}$  if the decision maker's relative preference for  $X_i$  with  $X_{\overline{1}}$  held fixed are the same regardless of the chosen value of  $X_{\overline{1}}$ .
- (2) <u>Pairwise Preferential Independence</u>. This property exists if the choice between two consequences  $(X_1, X_2, X_3, \ldots, X_N)$  and  $(X_A, X_B, X_3, \ldots, X_N)$  does not depend on the values of  $X_3, \ldots, X_N$ , for all pairs of attributes.
- (3) <u>Pairwise Marginality</u>. Pairwise marginality exists if the lottery (choice)  $(X_i, X_j)$ ,  $(X_i^*, X_j^*)$  is indifferent to  $(X_i, X_j^*)$ ,  $(X_i^*, X_j)$ , where lottery A,B is a choice situation with the probabilities of consequence A and B both one-half.

If the first two properties hold, the multiplicative form is used. If all three properties hold, the additive form is used. If none of the properties can be established, the technique is invalid. However, Keeney suggests the additive form may be applied to the data as this form provides a good approximation of the multiple attribute utility function. 10

<sup>10</sup> Keeney, R. L., <u>Multidimensional Utility Functions</u>: Theory, Assessment and <u>Application</u>, p. 23-25, MIT, October 1969.

# 3. Factors Describing Air-to-Air Weapon Systems

It is the intention of this thesis to apply the principles of Multiple Attribute Utility Theory to air-to-air fighter aircraft. As stated in Section 1 of this chapter, the study of any system requires the analyst to decompose the system into its basic elements or factors. The factors used in this study reflect the technical research done by Legrow in which the descriptive factors for fighter aircraft were as follows 11:

PLATFORM CRITERIA	WEAPON CRITERIA	MISCELLANEOUS CRITERIA
Max Speed (energy)	Range	Pilot Proficiency
Acceleration (T/W)	Missile Speed	Technological Level of the country
Manueverability (W/S)	Missile Envelope	
Endurance (combat radius)	Number of Gun Barrels	

As shown above, the factors contributing to capability are broken into three major dimensions; platform criteria, weapon criteria, and miscellaneous criteria. In the following chapters (III and IV), these factors, excluding the technological level of the country, are presented to experienced aviators in order to ascertain the appropriate utility curve and factor weighting for each factor. All data and results are presented so that further research may begin from this point.

<sup>11</sup> Legrow, op. cit., p. 122.

# III. SMALL SAMPLE SURVEY

This chapter applies the principles and concepts of Multiple Attribute Utility Theory to the problem of reliably assessing arms transfers. This is done by conducting a small sample survey in which experienced aviators were instructed to determine the utility curves and weights for the nine descriptive factors of fighter aircraft, described at the end of the preceding chapter. Section A discusses the main source of data collection -- a two part questionnaire. Section B describes a step-by-step application of the acquired data to the F4J "Phantom" using Israeli and Egyptian pilots. Section C discusses the problems encountered during the course of this experiment in a "lessons learned" format.

### A. DATA COLLECTION

A questionnaire (see Appendix A) was the primary source of data collection for this experiment. It consists of two parts, the first ascertaining the factor utility curves and the second, the factor weights. Since the respondents (students at the Naval Postgraduate School) were familiar with utility curves and their uses, the directions for part one are rather straight forward and focus primarily on graph familiarization. There is a short note, however, that instructs the respondent to ignore the relationship the factors bear towards one another as they draw each utility

curve. That is, if the respondent was considering the factor of manueverability, the potential trade-offs between manueverability and, say, dash speed should be ignored. This instruction was intended to establish the property of utility independence for each factor. This property is the only one of the three that either exists or does not exist. The other two properties (pairwise preferential independence and pairwise marginality) involve lotteries (choices) and it was felt these properties were best discussed orally with the respondents.

Part two employs a "pie-gram" to establish the factor weights. The pie-gram (the name was arbitrary) is a subjective measurement technique that employs a "constant sum" method [8]. This method of obtaining the factor weights is important for two reasons: (1) the results of such a method achieves the level of ratio measurement [8]; and (2) the method represents a departure from theoretical purity. That is, the research a priori forces the additive form of the Multiple Attribute Utility Function (MAUF) on the data collected since the sum of the factor weights = 1.0 ( $\Sigma K_i = 1.0$ ), and this, by definition, is the additive form. Thus, even if the multiplicative form was determined to be the correct form, the researcher has biased the data in such a manner that he/she would be unable to use this correct form. The reasons for such a priori biasing were as follows:

- 1. This researcher feels that every effort to insure ratio data should be pursued by analysts attempting to measure arms transfers. The perils of anything less were clearly identified by Legrow and his rebuttal of Mihalka's interval scores. 12 Thus, the respondents were not simply asked to numerically weight the factor's overall contribution to the process because it was felt this free form of subjective measurement, although yielding unbiased results, entails too large an assumption for ratio measurement. This assumption entails a belief that enough regularity exists in value judgment to measure them on a ratio level. Thus, by more reliable constant sum method, as discussed by Torgerson [7] was deemed a better approach to the subjective weighting of factors at the ratio level.
- 2. The consequences of forcing the additive form on the generated data are minimal because the measure of weapon systems are comparative and not absolute in nature (this further assumes transformations between the additive and multiplicative forms are consistent). To illustrate, consider a hypothetical situation where the multiplicative form of the MAUF yielded a score of 167 and the additive form yielded a score of 2012. The reader will immediately notice there is a significant difference of one order of magnitude between these two scores, which is precisely the

<sup>12</sup> See Chapter II, Section A.

point. The reader has <u>compared</u> one against the other and deduces a significant difference exists. If given the value of 2012 alone, how does one ascertain whether this is "good" or "bad?" Thus, as long as the analyst computes the scores in an identical manner, the errors in an absolute sense are irrelevent.

The results presented in the following chapter reflect the above decisions.

# B. APPLICATION OF THE DATA TO THE F4J "PHANTOM"

To apply MAUT to fighter aircraft, the analyst must first collect the pertinent factor information on the weapon system being studied.

The data for the F4J "Phantom" were collected from the duty officer of an operational squadron at Naval Air Station Miramar. These data, if not exact, will serve for illustrative purposes and are listed below:

FACTOR	F4J "PHANTOM"
Dash Speed	MACH 1.8
Acceleration (T/W)	.91:1
Wing Loading	92 lbs/sq ft
Combat Radius	500 nm
No. of Gun Barrels	0
Missile Speed	3.5 (Sparrow)
Missile Angle-Off	360° (Sparrow)
Missile Range	24 nm (Sparrow)

Next, the analyst enters the appropriate utility curve with the above information and reads the utility value associated with a particular entry. For example, Figure 3 depicts the resultant dash speed utility curve (the other factor utility curves are located in Appendix B) for this survey. The analyst would enter the graph on the horizontal axis with the "Phantom's" dash speed value (MACH 1.8).

Next, a vertical line is drawn from this point upward until it intersects the utility curve. A horizontal line is drawn from this point to the vertical axis and the judge's utility rating for MACH 1.8 is read. In this instance, the value would be .94.

This procedure was applied to the rest of the factors and the F4J "Phantom" scores were as follows:

FACTOR	F4J "Phantom" SCORES
Dash Speed	0.94
Acceleration	0.80
Wing Loading	0.40
Combat Radius	0.80
No. of Gun Barrels	0.00
Missile Speed	0.86
Missile Angle-Off	1.00
Missile Range	0.54

Once these factor scores are obtained, the analyst must determine their combinatorial relationship to each other.

As mentioned earlier, this survey a priori forced the results

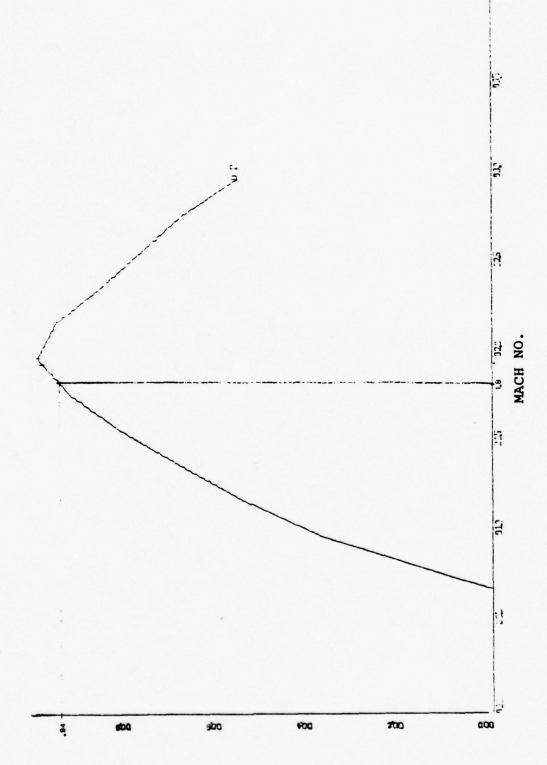

Figure 3. Utility Curve for Dash Speed: Small Sample Survey

into the additive form. The properties are still checked, however, to insure that <u>some</u> form of the MAUF applies.

Thus, the analyst checks which, if any, of the following properties hold:

# 1. Pairwise Marginality

Pairwise marginality is the first property checked because if it holds, utility independence and pairwise preferential independence are satisfied automatically [5].

Pairwise marginality presents the judge with two alternatives and checks whether or not the judge would be indifferent between them. That is, would the judge let the toss of a coin determine which alternative he or she would receive. These alternatives take two factors simultaneously (eventually considering all possible pairs of factors) and presents the judge with a series of hypothetical situations using the maximum and minimum values obtained from the respective utility curves. To illustrate this procedure, a sample case using the aircraft platform factors is presented.

	Minimum	Maximum
Define S = Dash Speed	MACH .7	MACH 1.9
A = Acceleration (T/W)	.4/1	1.1/1
W = Wing Loading	140	19
R = Combat Radius	80 nm	415 nm

The values for the minimum/maximum are obtained from the utility curves. These values were chosen because extreme cases usually precipitate easier decisions for the judge.

Any values between the minimum and maximum are permissible. Once the symbols are defined and the minimum and maximum values set, the judge is presented with a series of lotteries (choices) similar to the following.

# Indifferent between A and B

# Case 1

Let A = 50% chance the aircraft Yes \_\_\_\_ No \_\_\_ will have a S = 1.9 (maximum) and A = 1.1 (maximum) and a 50% chance the aircraft will have a S = .7 (minimum) and A = .4 (minimum)

Let B = 50% chance the aircraft will have a S = 1.9 (maximum) and A = .4 (minimum) and a 50% chance the aircraft will have a S = .7 (minimum) and A = 1.1 (maximum)

By answering "Yes" in the above lottery, the judge insinuates he would let the toss of a coin determine which alternative, A or B, would govern the factors for fighter aircraft.

A "No" answer implies the judge prefers one alternative to the other.

For the following cases, the same "50%" rules apply. The verbage, however, will be omitted and the lotteries will have the following format.

$$A = (S = 1.9, A = 1.1) \text{ or } (S = .7, A = .4)$$

 $B = (S = 1.9, A = .4) \text{ or } (S - .7, A = 1.1) \text{ Yes } No ____$ 

# Case 2

$$A = (S = 1.9, W = 19) \text{ or } (S = .7, W = 140)$$

 $B = (S = 1.9, W = 140) \text{ or } (S = .7, W = 19) \text{ Yes } No ____$ 

# Case 3

$$A = (S = 1.9, R = 415) \text{ or } (S = .7, R = 80)$$

 $B = (S = 1.9, R = 80) \text{ or } (S = .7, R = 415) \text{ Yes } No ____$ 

# Case 4

$$A = (A = 1.1, W = 19) \text{ or } (A = .4, W = 140)$$

B = (A = 1.1, W = 140) or (A = .4, W = 19) Yes \_\_\_ No \_\_\_

# Case 5

$$A = (A = 1.1, R = 415)$$
 or  $(A = .4, R = 80)$ 

 $B = (A = 1.1, R = 80) \text{ or } (A = .4, R = 415) \text{ Yes } ___ \text{No} ___$ 

# Case 6

$$A = (W = 19, R = 415) \text{ or } (W = 140, R = 80)$$

B = (W = 19, R = 80) or (W = 140, R = 415) Yes No

If the judge answered Yes for all six cases, additivity has been established for the platform factors and the additive form of the multiple attribute utility function is used. The same procedure is then applied to the other factors and the binomial coefficient provides a convenient formula for deducing the number of cases

# $\frac{N!}{R!(N-R)!}$

where N = total number of factors being considered; R = number of factors being considered at a time. For pairwise marginality computations, R = 2 in all cases.

The respondents of this survey voted against the additive form of the multiple attribute utility function. They felt alternative B always represented a better choice than alternative A. It was felt the risk of receiving the "minimum-minimum" factor combination possible with alternative A left the pilot no chance to develop a successful tactic. Alternative B, on the other hand, always offered a "minimum-maximum" factor combination and it was felt a tactic could be developed to protect the weak factor and exploit the strong one.

If the test for pairwise marginality fails at any point, (which occurs with the first "No" answer) the analyst must then determine if the multiplicative form applies. To do this, pairwise preferential independence is considered first as failure to establish this property automatically implies the multiplicative form of the utility function is not applicable.

# 2. Pairwise Preferential Independence

Using the definitions and the minimum/maximum values of the pairwise marginality example, the analyst again presents the judge with a series of lotteries. This time, however, the judge's lotteries involve all four factors at once. Basically, choice A fixes two factors at their minimum values and allows the other factors to assume some arbitrary value between their minimum and maximum. Choice B takes the fixed values in choice A and changes the values to the maximum. The other factors assume the same

arbitrary values assigned in choice A. The judge is then asked if his/her choice between A and B depends only on the values assigned to the fixed factors. This procedure is then repeated until all possible pairs of factors have been tested. If the judge's choice is positive in all cases, pairwise preferential independence has been established. This property, however, is insufficient to justify the multiplicative form by itself, therefore, utility independence must be checked. Before discussing utility independence, an example of pairwise preferential independence is presented.

# Case 1

Let 
$$A = (S = .7, A = .4, W = "X", R = "Y")$$
 and  $B = (S = 1.9, A = 1.1, W = "X", R = "Y")$ 

the judge is then asked if there are any values for "X" and "Y" (between the minimum and maximum values allotted by their respective utility curves) that could make him/her indifferent between lottery A and lottery B. Those values do not have to be ascertained. It is sufficient to know they exist. If there are none, pairwise preferential independence has been established for these two factors. The analyst must then repeat the procedure until all possible combinations have been exhausted. All pairs must exhibit pairwise preferential marginality to establish its existence.

For this test, the respondents indicated a preference in each case, thereby establishing this property. The reasons were similar to the ones expressed during the test for

pairwise marginality. That is, the respondents felt tactics could be successfully developed better around one alternative than the other. With this property established and given accessible respondents (if the respondents are inaccessible, the analyst must assume the questionnaire's guidance in this area was sufficient) the analyst must then reaffirm the existence of factor utility independence.

# 3. Utility Independence

Utility independence is established when the judge assures the analyst that the values given for any particular utility curve do not reflect, depend on or relate to the values of any other utility curve. In other words, was the respondent considering the potential trade-offs between attributes, say, dash speed and manueverability, while mapping their utility curves? If not, utility independence has been established.

As a review, pairwise marginality is required for the additive form of the utility function. Pairwise preferential independence and utility independence are both necessary for the multiplicative form. If neither form can be established, Keeney [16] suggests the additive form serves as a good approximation to the utility function. The factors may be grouped in their "natural" setting, as they were for this experiment, (i.e., dash speed, acceleration, wing loading and combat radius, considered together) with a subsequent inter-group check or they may be considered all together. The decision is left to the analyst.

In this survey, the additive form was applied to the data for the previously mentioned reasons. (Note: The technological evaluations for each country are not operative at this point, therefore, scores reflect only the aircraft, the weapons and pilot nationality.)

The results are as follows:

Utility score for Israeli pilots (who have an average of 1000 hours flight time, while Egyptians have an average of 500 hours) in the F4J "Phantom" with Sparrow missile

= .65

Utility score for Egyptian pilots in F4J "Phantom" with Sparrow missile

$$= \sum_{i=1}^{9} K_{i} \cdot U(X_{i}) = .53.$$

Thus, if one assumes equal logistical support, the Egyptians need 1.22 F4Js for every one of the Israelis' to achieve analytical parity. With the appropriate aircraft data, the analyst could evaluate each aircraft in the

<sup>&</sup>lt;sup>13</sup>A list of the resultant factor weights with a brief discussion may be found in Appendix C.

respective inventories to determine each country's air-to-air capability. Once established, future foreign requests for arms could be evaluated against these analytical parity checks.

In the next chapter, the theory is gently stretched in an effort to increase the experiment's sample size.

This is important because small sample sizes (e.g., 4, 8, 12, 20) are (statistically) insufficient to establish a high degree of confidence in the results. There is virtually no way of verifying whether the four respondents (for this survey) represent the norm or the extreme. This is not a problem peculiar to multiple attribute utility theory, it is a problem that arises whenever outside (non-textbook) data is fed through an analytical formula. A large sample size, therefore, is a simple but effective way to help alleviate the "garbage in-garbage out" syndrome so often associated with the real world/theoretical model combinations.

#### C. LESSONS LEARNED

The difficulties encountered with this questionnaire centered on the utility curves and their derivations.

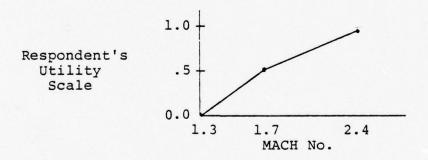

Originally, respondents were solicited from the Naval Postgraduate School and the fighter squadrons located at the Naval Air Station Miramar. The respondents solicited at Miramar did not have any prior knowledge of utility curves or their uses. This was not by design, it was more or less a function of the circumstances that brought the examiner

and the respondents together. The explanation of utility curves was not well received and the seven returned questionnaires (out of a possible 30) reflected the anticipated misperceptions. Thus, the sample size was reduced to the four aviators at the Naval Postgraduate School who possessed a knowledge of utility curves and their uses.

It is felt that further classical research should confine its respondents to those with prior knowledge of utility curves and their uses.

## IV. LARGE SAMPLE SURVEY

This chapter presents an alternative to a data collection procedure cited in Chapter III. Instead of the required utility curves, respondents would be instructed to identify three points for each factor -- the lower limit, the upper limit, and the 50th utile. These points are identical to their counterparts in the factor utility curves and would therefore retain the relevant properties necessary for ratio measurement. Once the analyst has acquired these points, they would be connected to form a piecewise linear approximation of the actual utility curve. As an example, consider a hypothetical case where the dash speed of a fighter aircraft is reported to have a lower limit of MACH 1.3, an upper limit of MACH 2.4 and a 50th utile of MACH 1.7. The piecewise linear approximation would appear as follows:

Admittedly, the precision of an actual utility curve is lost. It is felt, however, the benefits of such a system far outweigh the disadvantages. These benefits are believed to be: (1) The procedure will significantly broaden the

usable data base. The vast supply of aviators yields relatively few with utility theory training. Under the present system of data collection, this expertise would be lost.

With the three point system, all aviators are potential respondents since these values can be ascertained from the "no prior knowledge necessary" type question; (2) with a small sample size, it is extremely difficult (statistically) for the analyst to discern if the respondents reflect the norm or the extreme cases; (3) measuring the capability shifts contingent to an arms transfer is an inherently difficult task as there are many intangibles attendant to such transactions. Therefore, quantitative techniques to evaluate such transfers are approximations at best. Thus, the small amount of precision lost in the three point system is not considered critical by the author.

Section A discusses the questionnaire used to elicit the data. Section B analyzes these data in accordance with the procedures outlined in Chapter III. Section C summarizes respondents' comments in a "lessons learned" format.

#### A. DATA COLLECTION

A four part questionnaire was the source of data acquisition for this experiment. Part one establishes the lower and upper limits for each factor. The verbage was nontechnical and omitted any reference to utility curves and their underlying concepts. This, of course, was designed to permit respondents with little or no utility theory training or education to respond. The lower limit was intended to

represent the point of zero utility and the upper limit the point of maximum utility. Additionally, instructions designed to (hopefully) insure utility independence were included, similar to the effort in the small sample survey.

Part two attempts to establish the 50th utile for each factor. This was the most difficult section to write as the 50th utile is a counter-intuitive idea to those with no training in this area. The 50th utile may or may not represent the "half-way" point between the upper and lower limits of any particular factor. It all depends on the judge and his subjective opinions of performance versus utility. The questionnaire is located in Appendix D for the reader's scrutiny. Part three of this questionnaire presents a "pie-gram" identical to the one employed by the small sample survey. Thus, the data is pre-biased toward the additive form of the MAUF. Part four was a confidence check by the researcher to establish the respondents' perceptions of how well they felt they understood the questions. They were asked to rate each section on a scale of 1-100 (100 being the best) on the basis of their confidence in understanding the instructions. Respondent questionnaires that indicated a confidence level of less than 60% (arbitrarily) were discarded.

# B. APPLICATION OF THE DATA TO THE F4J "PHANTOM"

The vehicle used for analyzing the data was the histogram [8]. It was felt the pictorial display of the data's distribution provided the best tool to establish the single

value necessary for each limit. The particular computer program used (FORTRAN HISTF) to generate the graphics additionally features (1) a sample density function superimposed over the data cells, and (2) twenty-six statistical measures of data location, dispersion and distributional characteristics. Figure 4 displays the histogram analysis of the data received for the lower limit of dash speed (the remainder of the graphics are located in Appendix E). The single value decided upon for each factor's limit was the sample mean. This value was chosen because (1) the difference among the measures of location (mean, median, trimean, etc.) are minimal, and (2) there are a variety of analytical devices (provided the sample is large enough to invoke the central limit theorem) to establish the sample mean's reliability relative to the true population mean.

To illustrate, consider the sample mean for the lower limit of dash speed (MACH 1.36). Using the T-test 14, the analyst could easily establish, say, a .90 confidence interval for the population mean. The appropriate equation is 15

$$\overline{X} - t_{.95,199} \cdot \frac{S}{\sqrt{N}} < \mu < \overline{X} + t_{.95,199} \cdot \frac{S}{\sqrt{N}}$$

$$= 1.36 - 1.282 \cdot \frac{.421}{\sqrt{200}} < \mu < 1.36 + 1.282 \cdot \frac{.421}{\sqrt{200}}$$

$$= [1.321, 1.398]$$

<sup>14</sup> Freund, John E., Mathematical Statistics, p. 274, Prentice-Hall, Inc., 2nd Edition, 1971.

<sup>15</sup> Ibid., p. 274

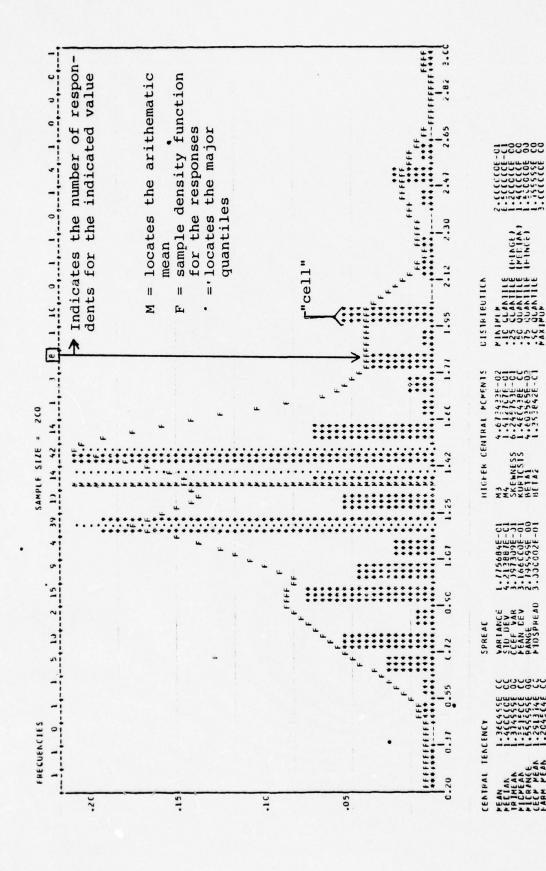

Figure 4. Histogram: Lower Limit for Dash Speed.

LCNEF LIPIT FCP LASE SFEEL

where  $\overline{X}$  is the sample mean, t<sub>.95,199</sub> = .05 tail area of a T distribution with 199 degrees of freedom, S is the sample standard deviation, N is the sample size and  $\mu$  is the population mean.

Thus, we are 90% confident that the <u>true</u> population mean falls somewhere between MACH 1.321 and MACH 1.398. The same procedure is easily applied to the other points. From a practical standpoint, the policy maker can be assured his evaluative model gives (statistically) reliable results.

Additionally, a scattergram [10,11] of the respondents' pilot hours versus the factor limits and weights was computed to discern if there was any correlation between the total number of hours accumulated by a fighter pilot and his response to the questions. Figure 5 displays the scattergram of pilot hours versus the lower limit for dash speed. The correlation for the sample regression line was 0.04981, in this case indicating an insignificant relationship between pilot hours and what was considered optimal for the lower limit of dash speed. The remaining scattergrams for this experiment are located in Appendix E along with the histograms.

A table with the resultant values for the lower limit, the upper limit, the 50th utile and the factor weighting are presented below (their resultant utility curves are located in Appendix F). Additionally, the new scores (as opposed to the ones calculated from the small sample survey) for the F4J "Phantom" equipped with the Sparrow missile are included.

Pilot Hours	533.90	830.2	1486.0	.249	.63(I) 0.00(E)

Reiterating the procedures outlined in Chapter III, the additive form of the large sample data yields the following results:

Utility score for Israeli (I) pilots in F4J "Phantom"

$$= \sum_{L=1}^{9} K_{i} \cdot U(X_{i}) = .512$$

Utility score for Egyptian (E) pilot in F4J "Phantom"

$$= \sum_{L=1}^{9} K_{i} \cdot U(X_{i}) = .356$$

Thus, the large sample survey suggests the Egyptians 16 need 1.43 F4J "Phantoms" to every 1.0 the Israelis have to achieve analytical parity.

Again, in the absence of data, the Egyptian and Israeli logistical efforts are assumed equal.

One of the expressed purposes of the large sample survey was to validate the proposed three point utility curve estimator as a statistically reliable tool. Unfortunately, the resultant sample size of the small sample survey (four) was insufficient to apply the available statistical tests to discern if the differences between the two samples were statistically significant. Perhaps a future research effort could gather a larger sample of utility curves for these factors and compare the results with the large sample data presented in this thesis.

If one were to view the results from a non-technical approach, however, the differences between 1.22:1 (the results from the small sample survey implying the Egyptians require 1.22 F4J "Phantoms" to every 1.0 the Israelis possess to maintain parity) and 1.43:1 (results from the large sample survey) are quite minimal. In fact, considering the gross difference in sample sizes, the results are surprisingly close. Perhaps this is suggestive that the respondents in both surveys represent identical populations and value differences are merely a function of the sample size. If these observations are considered judicious the analyst can conclude the three point utility curve estimators are reliable inputs to the multiple attribute utility function.

### C. LESSONS LEARNED

The majority of responses indicated a dissatisfaction with three factors -- wing loading, number of gun barrels, and missile range. It was felt that fusilage lift and a

host of aerodynamic changes rendered wing loading invalid as an indicator of a modern aircraft's turning radius. The number of gun barrels was generally received with multiple question marks and comments suggesting the one gun-one barrel concept has been replaced by the Gatling gun. Missile range, it seems, should have been presented in two categories, missile range "close in" and missile range "distant."

Perhaps the comments indicate that measures of aircraft (and other weapon systems) are fluid in nature. No single "once-and-for-all" measure of capability lurks about waiting to be discovered. Accurate evaluation, by any means, requires a continual updating of the factors surrounding a weapon system.

### V. CONCLUSIONS

The desire to accurately evaluate the transfer of arms to lesser developed countries is a growing concern among many military planners. Various quantitative techniques have been employed to measure these transfers but to date, none have produced a reliable indicator. This thesis examines Multiple Attribute Utility Theory as a possible alternative. The study has consumed one year and concludes with the conviction that multiple attribute utility theory is a significant step forward in the search for a valid measure of arms transfers. The advantages enjoyed by those who would employ this methodology are perceived to be as follows:

- 1. MAUT decomposes weapon systems into their basic elements. These elements are classless, measureable and easily understood. Every fighter aircraft has a dash speed and although experienced aviators may not be able to specify what the optimum value should be, they can bracket it.
- 2. MAUT establishes the weight or relative importance for each of these elements. Thus, different permutations of pilots, weapons and aircraft are easily calculated.
- 3. The input data for this device is derived from judges with operational expertise. It is not a tool wielded by those who have never seen, sat in or operated the weapon system they are about to judge.

- 4. As more factors become relevant or capable of measurement (e.g., technological level of the country), the theory allows "newcomers" to be included into the calculations.
- 5. With two minor assumptions, MAUT achieves the level of ratio measurement. Only with ratio measurement can one say "aircraft A is 1.4 times better than aircraft B."
- 6. It circuitously quantifies a host of "intangibles."
  The "intangibles" are an important part of any man-machine interface yet most analysts would be hard pressed to define or quantify these factors. MAUT solves this problem by having pilots evaluate pilots, tank drivers evaluate tank drivers, etc., in a common denominator -- hours of experience. These people may not be able to verbalize their thoughts and feelings about what makes a good pilot or tank driver, but they are considered when the analyst asks them "What is the minimum number of hours you want your wingman, etc., to have?"

The disadvantages of MAUT are:

1. The properties that govern what form of the utility function to use, i.e., how to combine the factors, are difficult to establish. It is suggested this is not as critical a point as it might first appear. The measurement of weapon systems are inherently comparative in nature. It would seem decision makers are not concerned with how good a weapon is absolutely, but rather how good is it compared to what their opponents have. Thus, the small errors that arise from using the incorrect form are irrelevant as long as the same form is used for all computations.

- 2. The utility curves required of each judge serve to limit the sample size of any experiment and small sample experiments are always suspect. With a minor modification, however, this problem is alleviated and sample size could potentially reflect the entire class of experienced operators.
- 3. The implications of aggregating responses (i.e., utility curves and factor weights) have not been fully deciphered. Future research should validate this point before MAUT is implemented as a decision making tool.

During the course of this research, some interesting observations were made.

- 1. The descriptive factors for fighter aircraft used by this study were established by previous research. It seems a reasonable conclusion they were the accepted norm at the time, yet, a majority of the large sample respondents indicated a dissatisfaction with these factors. Perhaps this is an indication that norms or measures of military worth are not fixed but evolutionary in nature.
- 2. If MAUT is not considered a judicious measurement technique, within its framework lies a potentially useful tool. The "tool" is the knowledge of what fleet personnel perceive to be good. The respondents to the large sample survey may have chosen poor values for each factor, but those values, right or wrong, reflect their perceptions of what is "right." It would seem a knowledge of the fighting man's perceptions are useful data.

#### APPENDIX A

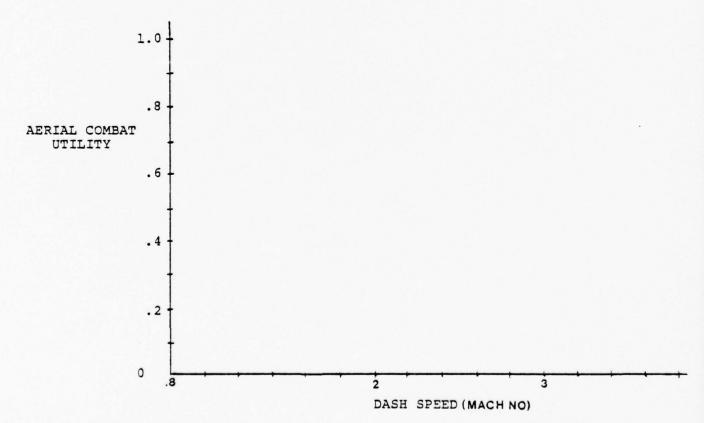

### CHARACTERISTICS OF FIGHTER AIRCRAFT

The ever increasing transfer of fighter aircraft to the lesser developed countries generates a mounting concern among many military planners. The current, quantitative techniques to evaluate the military worth of such transfers often revolve around the budgetary or inventory type models. This research effort intends to expand on the inventory method by including such factors as the maintenance capability of the country, pilot experience and the previously untested concept of comparing their fighters against the "ideal" fighter, a (theoretical) plane designed from the experience of many pilots in the various TACAIR communities that, hopefully, is captured by this questionnaire.

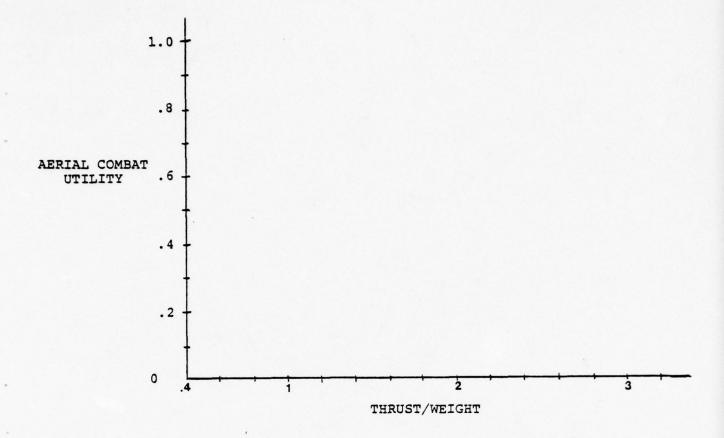

Thus, to complete this survey, you need not remember specific technical features of any particular aircraft. Just respond using your intuition and experience, and remember the survey is concerned with air-to-air performance factors. Please work independently as cross comparisons with other participants will invalidate the subsequent mathematical tests.

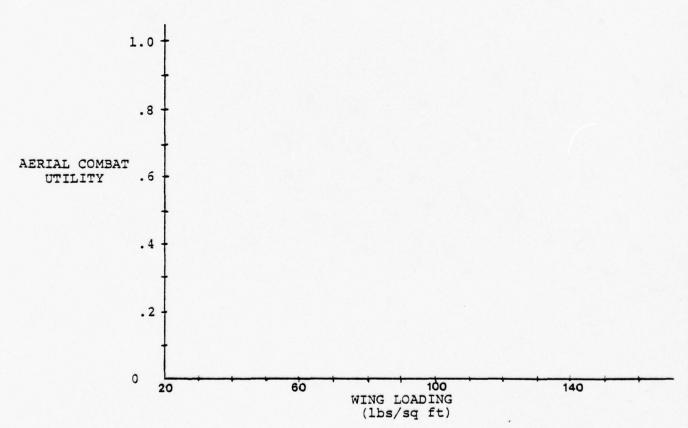

Below are a number of factors describing aircraft performance. Previous research has identified these characteristics as a reasonably complete way of classifying aircraft. Your task for this section is to draw a utility curve for each factor, keeping in mind this survey is only concerned with the factor's relationship in aerial (air-to-air) combat. Each curve should begin at the point of zero utility and at least pass through the point of maximum utility. The vertical scale represents "utility" and is annotated from 0 - 1.0, 1.0 representing maximum utility. The horizontal scale represents the factor and is annotated in the appropriate units.

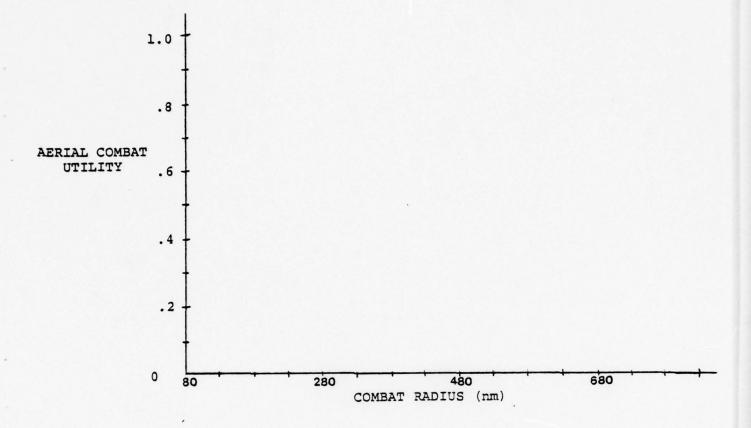

When considering these factors and their utility curves, try to consider each one individually, ignoring its effect or relation to any other factor. Admittedly, this is not possible in the real world for one factor (say manueverability) is always considered in terms of other factors (i.e., wing loading, top speed, etc.) but for now, assume we have some magic process that can incorporate one factor at no consequence to another.

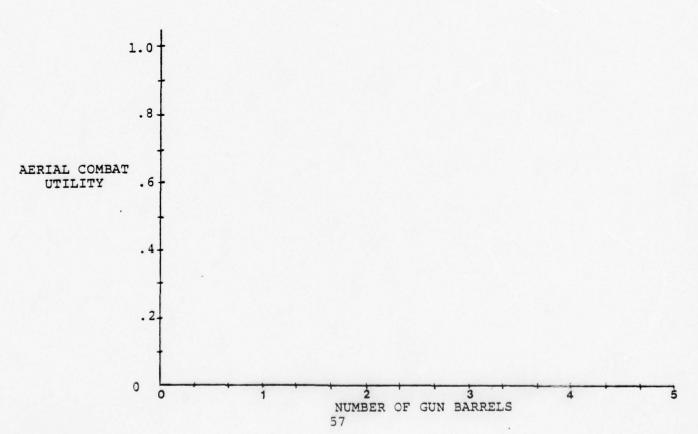

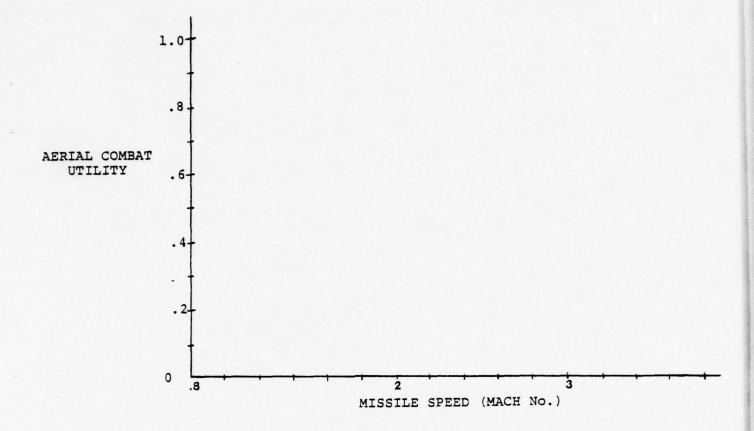

<sup>1</sup>Consider the aircraft in a combat configuration in day, VFR conditions.

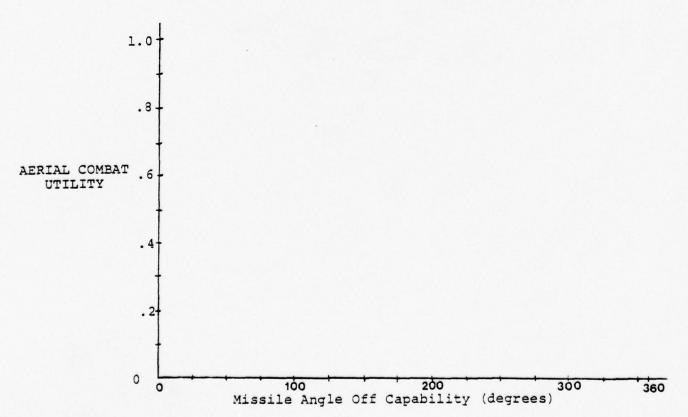

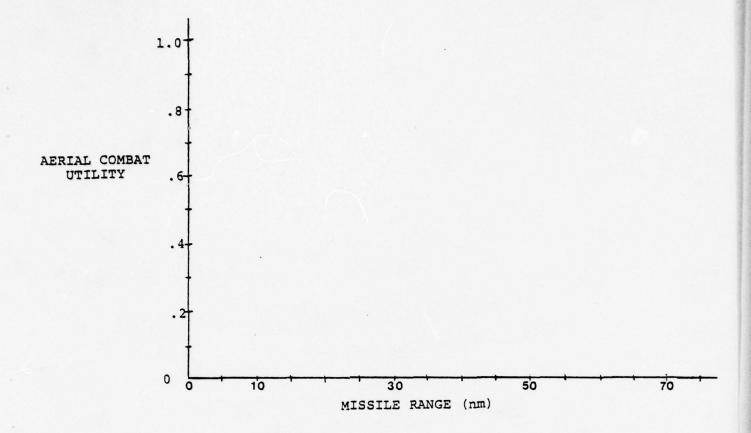

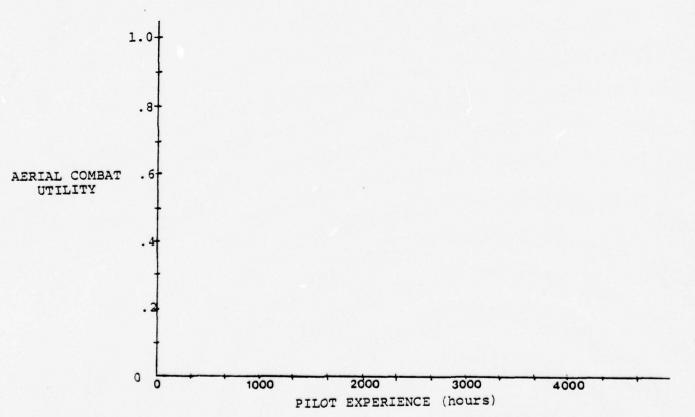

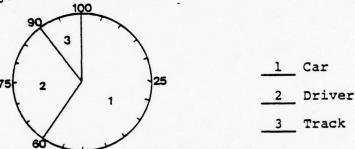

#### SECTION II

In this section you are to gauge the relative importance of each factor in its contribution to overall air-to-air combat superiority. The manner in which you will indicate your preferences is with the "pie-gram." The "pie-gram" is a pictorial way of indicating the importance of a factor by the thickness or thinness of the slice. This test is often used when there are many factors for it is generally easier to judge the relative importance when you can "see" the size of one slice compared to another. Pies are annotated from 0 - 100 to facilitate the divisions and provide later analysis.

As an example, consider a race car and assume that three factors -- car, driver and track -- completely describe the elements necessary to win a race. A piegram could look like the following:

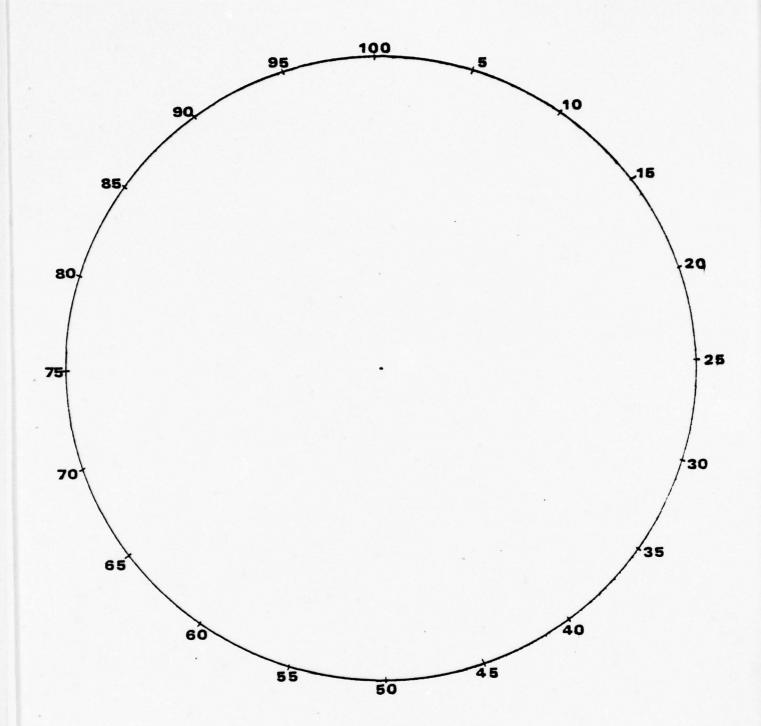

This would mean whomever divided the pie feels that the car is the most important factor for winning the race. Its portion takes up 60% of the overall pie and is three times as large as any other "slice."

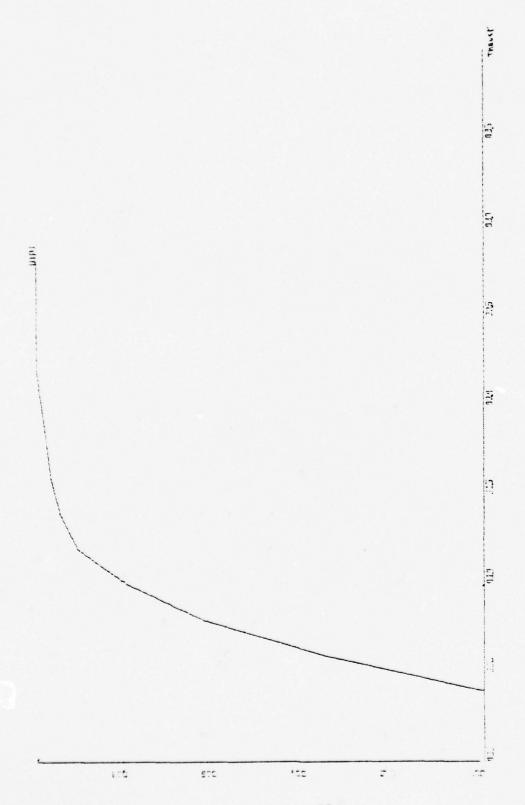

Our "pie" will have nine (09) slices as there are nine performance factors. Please divide the "pie" in accordance with the above example.

## FACTORS

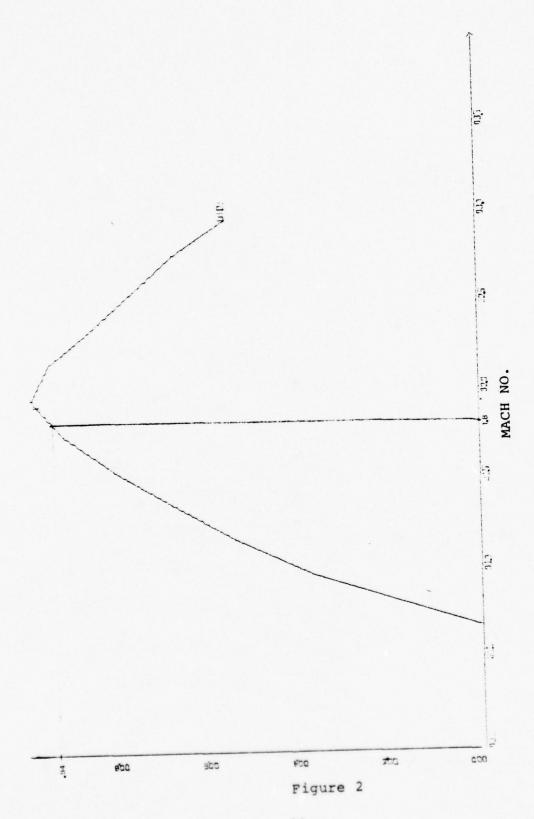

Speed	Missile Speed

### DISCUSSION

Examination of the data reveals that the factor entitled "C-Radius" (combat radius) possesses the smallest variance and therefore exhibits the least amount of data dispersion about the mean  $(\overline{X})$ . This infers there was considerable agreement among the respondents concerning the optimum value for combat radius. Thus, the analyst would have the more confidence in this value than in any of the others.

Similarly, the factor labelled "Pilot Hours" has the largest variance among the received responses. This would indicate the most controversial optimum value among the factors.

Perhaps the agreement exhibited for combat radius reflects the fact that this factor was not as important as the others. That is, the respondents collectively felt this was a non-critical factor and a value of "X" was close enough. On the other hand, pilot hours are more personal. A small weighting of this factor would imply a pilot's part is relatively minor/unimportant to the overall mission and vice versa. Therefore, this research assumes the answers will reflect the mental homogeneity of the respondents more than objective observation of this factor's overall contribution.

### APPENDIX D

### CHARACTERISTICS OF FIGHTER AIRCRAFT

The ever increasing transfer of fighter aircraft to the lesser developed countries generates a mounting concern among many military planners. The current, quantitative techniques to evaluate the military worth of such transfers often revolve around the budgetary or inventory type models. This research effort intends to expand on the inventory method by including such factors as the maintenance capability of the country, pilot experience and the previously untested concept of comparing their fighters against the "ideal" fighter, a (theoretical) plane designed from the experience of many pilots in the various TACAIR communities that, hopefully, is captured by this questionnaire.

Thus, to complete this survey, you need not remember specific technical features of any particular aircraft. Just respond using your intuition and experience, and remember the survey is concerned with air-to-air performance factors. Please work independently as cross comparisons with other participants will invalidate the subsequent mathematical tests.

SECTION I	Total Pilot Hours
Aircraft Flown	Branch of Service

Below are a number of factors describing aircraft performance. Previous research has identified these characteristics as a reasonably complete way of classifying aircraft. Your task for this section is to estimate a lower and upper limit for each factor listed. The lower limit represents the value (or amount) you feel is the minimum a fighter aircraft could have and still be effective in aerial combat. The upper limit is a technologically feasible point that you feel yields a clearcut combat superiority, i.e., any further improvements would be of marginal value.

For example, if you were considering the purchase of a race car, you might choose a lower limit of 140 mph and an upper limit of 250 mph. By this choice of limits, you feel that if a car (when considering the factor of speed alone) could not do at least 140 mph, it would not be in the class of race cars and you would not buy it. Similarly, the upper limit of 250 mph means you feel this car will easily outrun its competition and further speed increases would be of marginal value.

When considering these factors, try to consider each one individually, ignoring its effect or relation to any other factor. Admittedly, in the real world this is not possible, for an increase or decrease in one factor (say manueverability) will have some very direct effect on other factors (i.e., top speed, wing loading, etc.). But for now, as you mark the factors below, assume we have some magic process that can alter one factor at no consequence to another.

PLA	TFORM FACTORS	LOWER LIMIT	UPPER LIMIT
a.	Dash Speed (MACH No.) combat configuration, minimum combat package*		
b.	Acceleration (thrust/weight ratio) minimum combat package*		
c.	Wing Loading (lbs/square foot)		
d.	Combat Radius (nautical miles)		

\* Since the amount of fuel will affect your answer, this requirement is an attempt to standardize the replies. Here, the minimum combat package means the minimum fuel state at which you would consider a combat engagement with a return to home base.

# SECTION I (con't)

		LOWER LIMIT	UPPER LIMIT
WEA	PON FACTORS		
a.	Number of Gun Barrels		
b.	Missiles (do not categorize mentally as IR, Radar or Laser. What feasible end results would you like to see)		
	(1) Speed (MACH No.)		
	(2) Angle Off (degrees)		
	(3) Range (nautical miles)		
EXP	ERIENCE FACTORS		
	al (actual) Pilot Hours ower limit - minimum number of hours you would want your wingman to have		
U	<pre>pper limit - amount of (attainable)</pre>		

### SECTION II

For this section, assume our magic aircraft engineer has completely designed an aircraft except for one factor. For this factor he can choose a "risky" design or a "safe" design. If he picks the "risky" design, there is a 50% chance the factor will have the lower limit you specified (in Section I) and a 50% chance it will have the upper limit.

On the other hand, if the engineer chooses the "safe" design you are 100% certain the factor will have some arbitrary "safe value" (this value would be some number between the upper and lower limit). Your task is to estimate how low this "safe value" would have to be before you would consider giving it up and accepting the results of the "risky" design.

To further illustrate, consider the race car example of Section I and the factor of speed. The limits were given as 140 and 250 mph, therefore the alternatives would be as follows:

Risky Design - 50% chance car will have a speed of 140 mph 50% chance car will have a speed of 250 mph

Safe Design - 100% chance car will have the "safe value"

If the designer told you the "safe value" was 249 mph and asked you to recommend a design, you probably would choose the safe design. Not much point in giving up a sure 249 mph for what you could get from the risky design -- a 50% chance the speed would be 250 mph (1 mph faster) and a 50% chance the speed would be 140 mph (109 mph slower!).

On the other hand, if the designer told you the "safe value" was 143 mph and asked for your recommendation, you would probably tell him to go ahead with the "risky" design. Not much to lose (going from 143 mph down to 140 mph) and a lot to gain (going from 143 mph up to 250 mph). So in this case you would probably disregard the sure 143 safe value and gamble on the "risky" design.

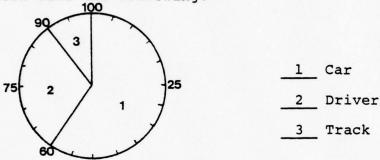

Somewhere between the upper and lower limits you selected, there is a "safe value" that makes choosing the "risky" design just as attractive as choosing the "safe" design. Thus, for each factor listed below, please indicate the cutoff "safe value."

		SAFE VALUE
PLA'	TFORM FACTORS	
a.	Dash Speed (MACH No.) combat configuration, minimum combat package	
b.	Acceleration (thrust/weight ratio) minimum combat package	
c.	Wing Loading (lbs/square foot)	
d.	Combat Endurance (nautical miles)	
WEA	PON FACTORS	
a.	Number of Gun Barrels	
b.	Missiles (do not categorize mentally as IR, Radar or Laser. What feasible end results would you like to see)	
	(1) Speed (MACH No.)	
	(2) Angle Off (degrees)	
	(3) Range (nautical miles)	
EXP	ERIENCE FACTORS	
Tota	al (actual) Pilot Hours	

### SECTION III

In this section you are to gauge the relative importance of each factor in its contribution to overall air-to-air combat superiority. The manner in which you will indicate your preferences is with the "pie-gram." The "pie-gram" is a pictorial way of indicating the importance of a factor by the thickness or thinness of the slice. This test is often used when there are many factors for it is generally easier to judge the relative importance when you can "see" the size of one slice compared to another. Pies are annotated from 0 - 100 to facilitate the divisions and provide later analysis.

As an example, consider the race car mentioned in Section I and assume that three factors -- car, driver and track -- completely describe the elements necessary to win a race. A piegram could look like the following:

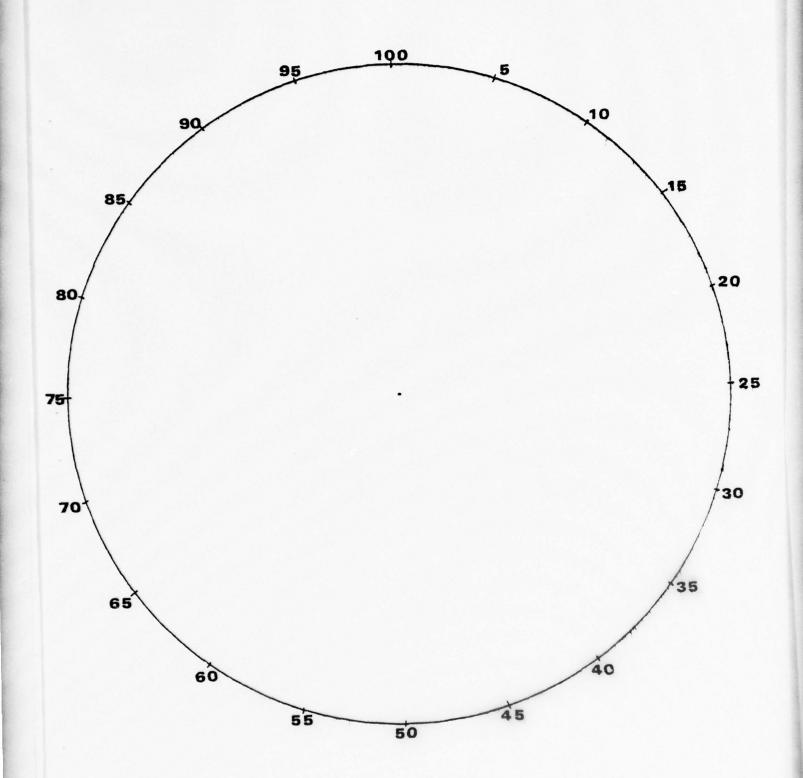

This would mean whomever divided the pie feels that the car is the most important factor for winning the race. Its portion takes up 60% of the overall pie and is three times as large as any other "slice."

Our "pie" will have nine (09) slices as there are nine performance factors. Please divide the "pie" in accordance with the above example.

# **FACTORS**

\_\_\_\_ Speed \_\_\_\_ Missile Speed
\_\_\_\_ Acceleration \_\_\_\_ Missiles Angle Off Capability
\_\_\_\_ Wing Loading \_\_\_\_ Missile Range
\_\_\_ Combat Radius \_\_\_\_ Pilot Experience
\_\_\_\_ Number of Gun Barrels

As you divide the "pie" please number each slice and place the corresponding number in the appropriate blank.

#### SECTION IV

Composing a questionnaire is an inherently difficult task as this device only allows one-way communication. This problem inevitably leaves the investigator with a nagging doubt concerning the participants' interpretations of the posed questions. Therefore, I would like to conclude this survey with a rather unscientific procedure to determine the extent of your interpretation difficulties, if any. On a scale of 1 - 100, please rate the first three sections on the confidence you have in your understanding of the question (100 is the best).

SECTION	I	
SECTION	II	
SECTION	III	

I thank you for your cooperation and participation in this survey.

Sincerely,

Patrick M. O Connell

PATRICK M. O'CONNELL Lieutenant U. S. Navy

### APPENDIX E
